Foot Fractures Frequently Misdiagnosed as Ankle Sprains

DANIEL B. JUDD, M.D. and DAVID H. KIM, M.D.
Tripler Army Medical Center, Honolulu, Hawaii

Most ankle injuries are straightforward ligamentous injuries. However, the clinical presentation of subtle fractures can be similar to that of ankle sprains, and these fractures are frequently missed on initial examination. Fractures of the talar dome may be medial or lateral, and they are usually the result of inversion injuries, although medial injuries may be atraumatic. Lateral talar process fractures are characterized by point tenderness over the lateral process. Posterior talar process fractures are often associated with tenderness to deep palpation anterior to the Achilles tendon over the posterolateral talus, and plantar flexion may exacerbate the pain. These fractures can often be managed nonsurgically with nonweight-bearing status and a short leg cast worn for approximately four weeks. Delays in treatment can result in long-term disability and surgery. Computed tomographic scans or magnetic resonance imaging may be required because these fractures are difficult to detect on plain films. (Am Fam Physician 2002;66:785-94. Copyright© 2002 American Academy of Family Physicians.)

Lateral talar dome fractures are almost always associated with trauma, while medial talar dome lesions can be traumatic or atraumatic.
patient may have sustained a fall or a twisting injury to the ankle and may generally ambulate with an antalgic gait. In the acute setting, the symptoms of a talar dome fracture are similar to and often occur with an ankle sprain.3,5

In lateral talar dome lesions, tenderness is generally found anterior to the lateral malleoli, along the anterior lateral border of the talus.3,6 In medial talar dome lesions, tenderness is usually located posterior to the medial malleolus, along the posterior medial border

AP = anteroposterior; NWBSLC = nonweight-bearing, short leg cast.

*—Acutely, most fractures will have symptoms very similar to those of ankle sprains: swelling, ecchymosis, ligamentous laxity, tenderness, and decreased range of motion.

†—All of these fractures can have subtle findings on plain radiograph, and computed tomography or magnetic resonance imaging may be required to accurately confirm or characterize a fracture.
of the talar dome. Chronic talar dome lesions—traumatic and atraumatic osteochondritis dissecans lesions—may have a clinical presentation similar to that of arthritis. Typical findings include crepitance, stiffness, and recurrent swelling with activity.

Diagnosis of talar dome lesions can often be made with standard anteroposterior (AP), lateral, and mortise ankle radiographs. However, repeated radiographs may be necessary because initial films may appear normal. Secondary changes in the subchondral bone (visible on plain radiographs) caused by a compression fracture of the articular osteochondral surface may take weeks to appear. In addition, small chondral fragments are radiolucent and not evident on standard radiographs.

Generally, the AP ankle view is best for visualizing deep, cup-shaped medial lesions, although the lesions are often appreciated on the mortise view as well (Figure 3). Lateral lesions are best visualized on a mortise view and are generally thin and wafer-shaped (Figure 4). If suggested by the clinical scenario, fractures not visualized with plain radiographs may require magnetic resonance imaging (MRI) or computed tomography (CT).

The fracture classification developed by Berndt and Harty is widely used to stage talar dome lesions (Table 3).

**TREATMENT**

An orthopedic surgeon should be consulted for treatment of talar dome lesions because of the high functional demands of

the talar dome and the potential for complications. Stage I, II, and III medial lesions can usually be treated nonsurgically with six weeks in a nonweight-bearing cast.\textsuperscript{1,3,5} Adequate reduction and immobilization are crucial for fracture healing and to avoid avascular necrosis of the fracture fragment.\textsuperscript{5}

Patients with stage III lateral lesions, stage IV lesions, and persistent symptoms are generally treated surgically. Treatment options for fragment excision range from arthroscopy with or without subchondral bone drilling to open reduction internal fixation.\textsuperscript{4,5}

**Lateral Process Fractures**

The lateral talar process is an osseous protuberance that articulates superolaterally with the fibula, helping to stabilize the ankle mortise, and inferomedially with the calcaneus, forming the lateral portion of the subtalar joint\textsuperscript{7} (Figures 1 and 2). Lateral process fractures are the second most common talar fractures. From 33 to 41 percent of these fractures are missed on initial presentation.\textsuperscript{8-11} Traditionally, the causative injuries are falls, motor vehicle crashes, or direct trauma. Some recent reports\textsuperscript{7-9,12} implicate snowboarding accidents in these fractures.

**DIAGNOSIS**

The patient usually has a history of a rapid inversion and dorsiflexion injury.\textsuperscript{7-9} Fractures of the lateral process range from avulsion fractures of the capsular ligaments to intraarticular injuries involving the ankle and subtalar joints.\textsuperscript{9}

Physical examination findings are similar to those in lateral ankle ligamentous injuries. Pain with plantar flexion, dorsiflexion, and

subtalar joint movement is generally present.  
Although the normal anatomy of the ankle may be obscured by soft tissue swelling, a helpful diagnostic indicator is point tenderness over the lateral process. The lateral process can be palpated anteriorly and inferiorly to the tip of the lateral malleolus.

Fractures can usually be visualized on a standard ankle series (Figure 5). A posterior subtalar effusion seen on the lateral view is highly suggestive of an occult lateral process fracture. A CT scan can clearly show this injury and may be required to confirm a suspected fracture.

TREATMENT

A nonweight-bearing, short leg cast can be used if anatomic position with less than 2 mm displacement can be maintained. A nonweight-bearing cast should be maintained for four to six weeks, followed by two weeks in a walking cast and initiation of rehabilitation exercises. For large and displaced fragments, the treatment of choice is usually surgical reduction and fixation.

Changes in the subchondral bone of the talar dome may not be seen initially on plain films. They may be visualized several weeks later on plain films or MRI or CT scans.

Posterior Process Fractures

The posterior process of the talus is composed of two tubercles, the lateral and medial (Figures 1 and 2). The lateral tubercle is the larger of the two and serves as the attachment of the posterior talocalcaneal and posterior talofibular ligaments. The medial tubercle serves as the attachment for the posterior third of the deltoid ligament. The undersurface of both tubercles forms the posterior fourth of the subtalar joint. An accessory bone known as the os trigonum is relatively common, posterior to the lateral tubercle. The os trigonum can be a source of pathology, and a normal os trigonum may be confused with a fracture of the lateral tubercle.

Again, these fractures have been commonly misdiagnosed as ankle sprains. In one case series, 17 of 20 patients with fractures were misdiagnosed with ankle sprains. Posterior process fractures can occur at either or both tubercles. Lateral and medial tubercle fractures are discussed separately.

FRACTURES OF THE POSTERIOR PROCESS: LATERAL TUBERCLE

Fractures of the lateral tubercle can be caused by hyperplantar flexion or inversion. Hyperplantar flexion injuries tend to cause compression fractures, while inversion injuries tend to produce avulsion fractures. Both of these injuries have been described after falls and have been associated with football and rugby kicking injuries, which place the ankle in a forced plantar flexed position. If present, an os trigonum can be injured by the same mechanisms described above.

Diagnosis. Clinically, patients with a fracture of the lateral tubercle present with pain...
and swelling in the posterolateral area of the ankle. The pain is often exacerbated by activities requiring plantar flexion. Physical examination findings in lateral tubercle fractures of the posterior process are highly consistent for tenderness to deep palpation anterior to the Achilles tendon over the posterior talus. The pain is often reproduced with plantar flexion and occasionally accentuated with dorsiflexion of the great toe. This is caused by compression of the fracture fragment as the flexor hallucis longus tendon passes between the medial and lateral tubercle.

Careful physical examination and correlation with radiographic findings may be necessary to differentiate a fracture of the lateral tubercle, a fracture of a fused os trigonum, a tear in the fibrous attachment of the os trigonum to the lateral tubercle, or a normal os trigonum.

A lateral radiograph of the foot usually best visualizes the lateral tubercle and, if present, the os trigonum. When evaluating the fracture line, a rough, irregular cortical surface suggests the presence of an acute fracture (Figure 6). In acute injuries, this rough irregular surface may help distinguish a fracture from a normal os trigonum, which generally has a smooth, rounded cortical surface. In chronic cases, these differences may be less distinct, making the distinction between a fracture and a normal os trigonum difficult. When the diagnosis is unclear and clinical suspicion is present, an MRI or CT will clearly demonstrate this fracture.

Treatment. Nondisplaced or minimally displaced fractures can be treated with a non-weight-bearing, short leg cast for four to six weeks. After this period of immobilization, weight bearing is allowed as tolerated. If symptoms persist, an additional four to six weeks of immobilization would be recommended. If the fracture site continues to be symptomatic after six months, fragment excision is usually curative. Larger and more displaced fractures may require open reduction internal fixation.

FRACTURES OF THE POSTERIOR PROCESS:
MEDIAL TUBERCLE

Medial tubercle fractures are relatively rare. They were first described by Cedell, who presented four cases of medial tubercle fractures that had originally been treated as ankle sprains.

Diagnosis. Generally, medial tubercle fractures are secondary to dorsiflexion, pronation-type injuries, because the medial tubercle is avulsed by the deltoid ligament. On clinical assessment, there may be only slight pain with ambulation and range-of-motion and swelling in the posterolateral area of the ankle. The pain is often exacerbated by activities requiring plantar flexion. Physical examination findings in lateral tubercle fractures of the posterior process are highly consistent for tenderness to deep palpation anterior to the Achilles tendon over the posterior talus. The pain is often reproduced with plantar flexion and occasionally accentuated with dorsiflexion of the great toe. This is caused by compression of the fracture fragment as the flexor hallucis longus tendon passes between the medial and lateral tubercle.

Careful physical examination and correlation with radiographic findings may be necessary to differentiate a fracture of the lateral tubercle, a fracture of a fused os trigonum, a tear in the fibrous attachment of the os trigonum to the lateral tubercle, or a normal os trigonum.

A lateral radiograph of the foot usually best visualizes the lateral tubercle and, if present, the os trigonum. When evaluating the fracture line, a rough, irregular cortical surface suggests the presence of an acute fracture (Figure 6). In acute injuries, this rough irregular surface may help distinguish a fracture from a normal os trigonum, which generally has a smooth, rounded cortical surface. In chronic cases, these differences may be less distinct, making the distinction between a fracture and a normal os trigonum difficult. When the diagnosis is unclear and clinical suspicion is present, an MRI or CT will clearly demonstrate this fracture.

Treatment. Nondisplaced or minimally displaced fractures can be treated with a non-weight-bearing, short leg cast for four to six weeks. After this period of immobilization, weight bearing is allowed as tolerated. If symptoms persist, an additional four to six weeks of immobilization would be recommended. If the fracture site continues to be symptomatic after six months, fragment excision is usually curative. Larger and more displaced fractures may require open reduction internal fixation.
motion testing. Patients with medial tubercle fractures typically have swelling and pain posterior to the medial malleolus and anterior to the Achilles tendon. Visualization of the medial tubercle fracture on plain radiograph may be challenging, but the fracture can generally be seen on an oblique projection with the foot and ankle externally rotated 40 degrees and the beam centered 1 cm posterior and inferior to the medial malleolus (Figure 7). However, CT (Figure 8) or MRI may be necessary if the diagnosis is unclear.

Treatment. Medial tubercle fractures are treated in a manner similar to that for lateral tubercle fractures.

Fracture of the Anterior Process of the Calcaneus

The anterior process of the calcaneus is a saddle-shaped bony protuberance that articulates with the cuboid. It is attached to the cuboid by an interosseous ligament and to the cuboid and navicular bones by the strong bifurcate ligament (Figures 1 and 2). Fractures of the anterior process account for approximately 15 percent of all calcaneal fractures and are commonly misdiagnosed as ankle sprains.

Anterior process fractures result from avulsion or compression. Inversion plantar flexion can cause avulsion fractures of the anterior process. This injury tends to be extra-articular and accounts for most of the anterior process fractures that are initially diagnosed as ankle sprains.

Anterior process fractures secondary to compression generally occur when the foot is forcefully dorsiflexed and the anterior process is pressed against the cuboid. Because of the energy involved with this mechanism, anterior process fractures secondary to compression are often intra-articular and are commonly associated with other fractures.

DIAGNOSIS

Patients with anterior process fractures generally have a history of a previous inversion injury or involvement in a motor vehicle crash. Clinically, patients generally show signs and symptoms similar to those of a lateral ankle sprain. The pain may be minimal with standing but increases substantially with ambulation. An important diagnostic feature is point tenderness over the calcaneocuboid joint that is localized approxi-

FIGURE 7. Special oblique view of the ankle showing a medial tubercle fracture (arrow) of the posterior process of the talus.

FIGURE 8. Computed tomographic scan demonstrating a medial tubercle fracture (arrow) of the posterior process of the talus.
mately 1 cm inferior and 3 to 4 cm anterior to the lateral malleolus, just distal to the anterior talofibular ligament insertion. Careful assessment of the point of maximal tenderness may help differentiate this fracture from a lateral ligament sprain.

Although this fracture can be difficult to assess on routine radiographs of the foot and ankle, a careful inspection of the lateral view of the calcaneus often reveals this subtle fracture (Figure 9). As the clinical scenario dictates, a CT scan or MRI may be necessary. In addition, an accessory ossicle (calcaneus secondarium) may be located near the anterior process and could be misinterpreted as a fracture.

TREATMENT
For small, nondisplaced fractures, early immobilization in a nonweight-bearing, short leg cast or compressive dressing for four to six weeks followed by range-of-motion exercises and a gradual return to weight bearing has been successful.

Although fracture healing may appear radiographically to be complete, approximately 25 percent of patients require more than a year before becoming asymptomatic. Following nonsurgical management, most patients report satisfactory results and a return to preinjury activity levels. Symptomatic nonunions or large, displaced fractures may require surgical intervention.

Final Comment
The fractures discussed here can be serious injuries and cause prolonged disability. In general, extra-articular fractures of the talus and calcaneus can be managed with nonsurgical treatment. However, intra-articular fractures require special attention to ensure that the articular surface is restored to anatomic congruity and that the correct mechanical alignment is maintained. This step optimizes the chance for a full recovery and decreases the incidence of post-traumatic arthritis and associated morbidities.

Appropriate radiographs are essential to the diagnosis of these fractures but, in the work-up of an ankle injury, radiographs are not always required. The Ottawa ankle rules (Figure 10) offer the physician clinical guidance as to which injuries require radiographs. Prospective studies have validated the effectiveness of these guidelines and shown the rules to be 100 percent sensitive for clinically significant fractures.

Although fractures of the talus were rarely encountered in the Ottawa ankle trials, the fractures discussed in this article would likely be identified using the Ottawa ankle rules, because of the inability of the patient to bear weight after the injury and during the examination.

Following the Ottawa ankle rules is likely to allow detection of talus and calcaneus fractures because patients will not often be able to bear weight. However, in patients with suspected sprained ankles that do not improve, radiographic analysis is indicated.
FIGURE 10. Adaptation of the Ottawa ankle rules used to determine when to obtain radiographs of the foot or ankle in patients with acute ankle injury. An ankle radiographic series is only required if there is pain in the malleolar zone and any of the following findings are present: bone tenderness at point A or B, or inability to bear weight immediately following the injury and during examination. A foot radiographic series is only required if there is pain in the midfoot zone and any of the following findings are present: bone tenderness at point C or D, or inability to bear weight immediately following the injury and during examination.

Nevertheless, some patients with these fractures are able to ambulate and, because patients with these fractures generally do not present with tenderness along the posterior border of the lateral or medial malleolus, radiographic evaluation may not be indicated under the Ottawa guidelines. However, as with all guidelines, clinical judgment and experience may be grounds for radiographic analysis in unique cases. Furthermore, in the case of a suspected ankle sprain that does not improve as expected or is accompanied by tenderness over a potential fracture site, radiographic analysis at a follow-up evaluation may be indicated. The fracture may then be diagnosed and treated soon enough after the injury to avoid an adverse prognosis.

The authors indicate that they do not have any conflicts of interest. Sources of funding: none reported.
