Edema is a frequently encountered problem in clinical practice, but effective treatment of this condition is a relatively recent development.1 The etiology of edema always must be determined; the condition may indicate an underlying life-threatening disease such as congestive heart failure, or it may be caused by something as benign as sitting for too long. Edema may be localized and confined to one limb, or generalized and massive. It usually results from an imbalance of forces controlling fluid exchange, including an alteration in capillary hemodynamics favoring the retention of sodium and water by the kidneys and the movement of fluid from the vascular space into the interstitium.2 The causes of edema are categorized in Table 1.3

Pathophysiology

Edema occurs when forces such as an elevation in capillary hydraulic pressure, an increase in capillary permeability or interstitial oncotic pressure, or a reduction in plasma oncotic pressure increase net filtration.2 The kidneys have a central role in maintaining body fluid homeostasis: they control extracellular fluid volume by adjusting sodium and water excretion. Antidiuretic hormone, which is secreted in response to stimuli such as changes in blood volume, tonicity, and blood pressure, is the primary regulator of body water. Sodium and other anions form the major solutes in extracellular fluid and are maintained within a narrow range. Sodium chloride intake generally is equivalent to output over the course of a few days; when intake increases, there is a compensatory increase in sodium chloride excretion after a lag period. Thus, extracellular fluid volume can be maintained at a constant level despite wide fluctuations in intake.4

The concept of effective arterial blood volume (EABV) is central to an understanding of the sodium retention that occurs to maintain plasma volume. EABV is sensed by volume homeostatic mechanisms and ultimately modulates renal sodium reabsorption. EABV correlates with extracellular fluid volume. In healthy persons, sodium loading increases extracellular fluid volume and EABV, resulting in prompt natriuresis and restoration of normal volumes. In persons who are volume depleted, EABV and extracellular fluid volume are reduced. Renal sodium retention is activated via the

Edema

-renin-angiotensin-aldosterone axis, and normal blood volume is restored. When kidney function is impaired, the partitioning of fluid in various compartments is disturbed. In the ensuing edematous states, the reduction in EABV activates volume/pressure sensors, including low-pressure baroreceptors in the venous circulation, high-pressure baroreceptors in the great vessels, intrarenal receptors, and intrahepatic receptors.

In patients with primary sodium retention, the afferent stimuli are suppressed. As extracellular volume increases, edema develops and EABV decreases. This change stimulates efferent pathways, causing sodium retention, activation of the sympathetic nervous system, stimulation of the renin-angiotensin-aldosterone axis, and secretion of arginine vasopressin.

Whether it is caused by decreased cardiac output or other conditions, edema persists because of compensatory mechanisms geared toward maintaining plasma volume.

Treatment

PRINCIPLES OF THERAPY

Treatment of edema consists of reversing the underlying disorder (if possible), restricting dietary sodium to minimize fluid retention, and, usually, employing diuretic therapy. This approach highlights the need to establish a diagnosis and to use nonpharmacologic approaches when appropriate, rather than resorting to the immediate use of diuretics.

Not all patients with edema will require drug treatment; in some patients, sufficient sodium restriction (i.e., less than the amount excreted by the kidneys) and elevation of the lower extremities above the level of the left atrium are effective. However, diuretics are required in most patients in addition to nonpharmacologic treatments, especially continued restriction of salt. The choice of diuretic, route of administration, and dosing regimen will vary based on the underlying disease, its severity, and the urgency of the problem. Knowledge of the pharmacokinetics and pharmacodynamics of the various agents is essential.

Diuretics exert their effects at different sites in the kidneys (Table 2). Loop diuretics such as furosemide (Lasix), bumetanide (Bumex), and torsemide (Demadex) block the sodium-potassium chloride transporter in the ascending loop of Henle, whereas thiazide diuretics block the electroneutral sodium chloride transporter in the distal convoluted tubule. Amiloride (Midamor) and triamterene (Dyrenium) block apical sodium channels in the cortical collecting tubule. These drugs are highly bound to albumin. All diuretics except spironolactone (Aldactone) reach luminal sites of action through the tubular fluid.

After oral administration of furosemide, absorption averages about 50 percent, but may range from 10 to 80 percent. Absorption of bumetanide and torsemide is more complete, ranging from 80 to 100 percent. Thiazide diuretics, such as chlorothiazide (Diuril) and hydrochlorothiazide (Esidrix), may be excreted unchanged in the urine. Other agents, such as bendroflumethiazide (Naturetin) and indapamide (Lozol), are metabolized by the liver. Plasma half-life will determine the frequency of administration. Thiazide diuretics with a long half-life can be administered once or twice daily.

Loop diuretics with shorter half-lives, which range from approximately one hour for bumetanide to three to four hours for torsemide, must be given more frequently than thiazide diuretics. The effect of loop diuretics

*—The mechanism by which phosphodiesterase inhibitors increase sodium chloride excretion is not known with certainty and may involve hemodynamic and tubular effects (perhaps mediated by cyclic adenosine monophosphate).

dissipates rapidly, after which the kidneys immediately begin to reabsorb sodium and nullify the diuretic effect. This process is called post-diuretic sodium chloride retention. If sodium chloride intake is high and the half-life of the diuretic is short (as with a loop diuretic), post-diuretic sodium chloride retention compensates entirely for the sodium loss. Therefore, sodium restriction is important when a patient is taking loop diuretics.

TREATMENT FAILURE

Diuretic resistance is a failure to create a negative sodium balance despite the use of high dosages of diuretics (e.g., furosemide at a dosage of 240 mg per day). Resistance should be suspected in patients with persistent edema who are receiving appropriate diuretic treatment and restricting physical activity and sodium intake (i.e., less than 2 g per day). An understanding of the pharmacokinetics of the various diuretic agents is essential in addressing diuretic resistance. Furosemide administered orally has an erratic absorption pattern; bumetanide may be a better choice because it is absorbed more completely. Adding a diuretic that acts at a different site may help overcome the adaptation of distal convoluted cells to chronic diuretic use. Using short-acting diuretics more frequently or using longer-acting diuretics limits the sodium reabsorption that can occur when the diuretic effect wears off. The patient must be followed carefully for adverse effects such as hypokalemia and hypovolemia. Occasionally it may be necessary to use a continuous intravenous infusion of a loop diuretic. This strategy should be reserved for patients with true refractory resistance who are being treated in an intensive care unit. Other potential causes of treatment failure are listed in Table 3.8 The problem may not be true drug resistance, but a matter of nonadherence to therapy; this becomes a concern in treating older adults who are taking multiple medications and are at risk for urinary incontinence. These patients may limit diuretic use to maintain continence. Diuretic resistance can be aggravated by the concomitant use of nonsteroidal anti-inflammatory drugs (NSAIDs), which may negate the diuretic effect. Discontinuing NSAID therapy may correct the resistance. Another potential cause of treatment failure is diuretic tolerance. Short-term tolerance should be considered when there is a decrease in response after the first dose of a diuretic has been taken. Short-term tolerance is thought to be caused by depletion of intravascular volume, with a compensatory response to protect against further fluid loss. Long-term tolerance can occur in patients who are treated with loop diuretics over a long period. The problem is related to a mechanism whereby the distal nephron segments undergo hypertrophy and reabsorb more sodium after prolonged exposure to solutes, thus decreasing overall diuresis. Increasing the dosage of loop diuretics in patients with long-term diuretic tolerance is unlikely to improve diuresis, whereas adding a thiazide diuretic, which acts at a different site, results in a synergistic and brisk diuretic response. The addition of acetazolamide (Diamox), which acts on the proximal tubule, also can be effective when there is decreasing response to other diuretics.

CONGESTIVE HEART FAILURE

In patients with moderate to severe congestive heart failure, activation of the renin-angiotensin system results in vasoconstriction in the afferent and efferent renal arterioles. Neurohumoral responses include the release of aldosterone from the adrenal glands; increased sympathetic activity, which causes increased sodium reabsorption in the proximal tubules; and secretion of antiuretic hor-

| TABLE 3 | Treatment Failure: Causes in Patients Taking Loop Diuretics |
|—— | ———— | ———— |
| Noncompliance | Nonadherence to drug regimen | Nonadherence to sodium restriction |
| True diuretic resistance | Altered intestinal absorption of loop diuretics | Decreased renal perfusion caused by low volume, arterial disease, or drug use (e.g., ACE inhibitors, NSAIDs) |
| | Pharmacokinetic causes related to diuretic half-life | Reduced tubular secretion caused by low volume, kidney disease, or drug use |
| | Tolerance caused by chronic use of loop diuretics | |

Edema

The goals of treatment in patients with congestive heart failure and edema include symptom relief, improved quality of life, retardation of disease progression, and decreased mortality.

mone, which causes increased water reabsorption in the collecting ducts and results in hyponatremia.\(^{13}\)

The goals of treatment include symptom relief, improved quality of life, retardation of disease progression, and decreased mortality.\(^{14}\) Despite their widespread use, diuretics have not been shown to improve survival in patients with congestive heart failure; the exception is spironolactone, which in one study\(^{15}\) decreased morbidity and mortality rates in patients with New York Heart Association class III and IV heart failure. Diuretics have been used in combination with other agents in all of the other major survival heart failure trials\(^{16}\) and provide superior symptom relief. Before inducing an increase in urinary output, loop diuretics administered intravenously reduce pulmonary capillary wedge pressure and increase venous capacitance within a few minutes of administration.\(^{17}\) Loop diuretics are effective as solo agents in the treatment of moderate to severe heart failure. Most patients with heart failure have some degree of renal impairment secondary to intrinsic disease, pre-renal azotemia, or an age-related decline in renal function. To overcome competition from endogenic organic ions at tubular binding sites, loop diuretics typically must be administered at higher dosages in patients with heart failure.

CIRRHOSIS

Most of the principles of diuretic use and sodium restriction apply in the treatment of ascites and edema associated with cirrhosis. Ascites is a common complication of cirrhosis and is associated with a worse prognosis.\(^{18}\) Its severity typically is graded on a scale of 1 to 3: grade 1, or mild ascites, is detectable only by ultrasound examination; grade 2 ascites is manifested by moderate symmetrical distension of the abdomen; and grade 3, or gross ascites, is characterized by marked abdominal distension. Ascitic fluid should be sampled to determine the cause. Restriction of sodium and water is recommended almost universally.

Grades 2 and 3 ascites occurring in patients with cirrhosis typically require the addition of spironolactone to combat hyperaldosteronism;\(^{19}\) a typical dosage of 100 to 200 mg given once per day with food generally is effective. Response should be monitored by daily weight measurement. Weight loss should be limited to 0.5 kg (1 lb, 2 oz) per day in patients without peripheral edema and to 1.0 kg (2 lb, 3 oz) per day in patients with edema. If no response occurs to treatment with 100 mg of spironolactone per day, a low-dose loop diuretic can be added. Precipitation of hepatorenal syndrome can occur with overly aggressive diuretic therapy. Side effects of spironolactone include hyperkalemia, metabolic acidosis, and gynecomastia; these effects typically respond to a lowering of the dosage or discontinuation of the drug.

Paracentesis is the treatment of choice in patients with grade 3 ascites and should be complemented by sodium restriction and diuretic therapy.\(^{18}\) Large-volume paracentesis in a single procedure is recommended even if the volume of fluid removed exceeds 5 L.\(^{19}\) Paracentesis should be followed by fluid replacement and expansion to prevent renal complications.\(^{20}\) Volume expansion should include a synthetic plasma substitute or albumin, especially if more than 5 L of fluid is removed.\(^{21}\) In patients with refractory ascites, the use of a transjugular intrahepatic portosystemic shunt (TIPS) may be considered. In a randomized study,\(^{22}\) TIPS was superior to large-volume paracentesis in relieving ascites and prolonging survival (58 versus 32 percent of patients were alive at two years). Many patients with ascites and cirrhosis eventually become candidates for hepatic transplantation. In another randomized study\(^{23}\) comparing TIPS with paracentesis and albumin, replacement resulted in greater survival rates at two years without transplantation (59 versus 29 percent).

NEPHROTIC SYNDROME

Nephrotic syndrome is a less common cause of edema and is characterized by marked proteinuria, hypoalbuminemia, hyperlipidemia, and edema. Debate continues over whether the edema is a result of decreased oncotic pressure or overfilling with sodium that results in water retention; most researchers now subscribe to the overfilling theory.\(^{24}\) Treatment includes sodium restriction and a combination of loop diuretics, antialdosterone drugs,\(^{25}\) and other medications to treat the underlying disease process.

CHRONIC VENOUS INSUFFICIENCY

Venous insufficiency is a common cause of edema of the lower extremities. New-onset edema—especially if it is unilateral—necessitates the exclusion of deep venous thrombosis (DVT). Complications of long-standing
lower-extremity edema include stasis dermatitis, ulceration, and cellulitis. Diuretics have limited benefit. Elevation of the affected limb above the level of the heart and the use of support stockings can alleviate venous hypertension and reduce edema, and support stockings have been found to significantly reduce the incidence of edema and DVT on long-distance flights (i.e., longer than seven hours).27

MEDICATION-INDUCED EDEMA

Many medications have been implicated in pedal edema, especially vasodilators, estrogens, NSAIDs, and calcium channel blockers. Dihydropyridine drugs are more likely than other calcium channel blockers to cause pedal edema. The edema appears to be dose-dependent and increases over time.28 Because medication-induced edema is caused by capillary hypertension, diuretics are not an effective treatment. However, angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers seem to be effective.29,30

LYMPHEDEMA

Lymphedema is the general term for a group of pathologic conditions characterized by excessive regional interstitial accumulation of protein-rich fluid.31 Lymphedema may be primary or secondary; globally, secondary lymphedema caused by filariasis is much more common, affecting 90 million persons worldwide.31 Lymphedema following axillary node dissection is the most common type in the United States, affecting up to 80 percent of patients after surgery.31 With the advent of breast-conserving surgery and sentinel lymph-node biopsy, it is hoped that the condition will occur less frequently.

Distinguishing lymphedema from other forms of edema may be challenging, especially early in its course. Stemmer’s sign, the inability to tent the edematous skin on the dorsal surface of the toes, suggests lymphedema. Additional findings include swelling of the dorsum of the foot with a “squared-off” appearance of the digits. A computed tomography (CT) or magnetic resonance imaging (MRI) scan may be necessary to confirm the diagnosis. A characteristic honeycomb pattern in the subcutaneous compartment distinguishes lymphedema from other edemas; MRI is considered superior to CT in diagnosing patients with this finding.33

Treatment may be initiated if the circumference of the arm increases by 2 cm from the preoperative measurement. Long-term use of compression garments coupled with meticulous skin care and avoidance of blood-pressure measurements and other constrictions on the affected site are likely helpful.34 The use of range-of-motion exercises; skin care; compression wrapping; and comprehensive decongestive physiotherapy, a two-phase process of specialized manual lymph massage and drainage, may be effective. Diuretics may be of benefit early in the course of the disease but rarely are effective on a long-term basis. Surgical treatment is of little benefit, although it may play a debulking role in patients with advanced elephantiasis.35

The authors indicate that they do not have any conflicts of interest. Sources of funding: none reported.
