Slipped Capital Femoral Epiphysis: Diagnosis and Management

DAVID PECK, MD, Providence Athletic Medicine, Novi, Michigan

Slipped capital femoral epiphysis is the most common hip disorder in adolescents, and it has a prevalence of 10.8 cases per 100,000 children. It usually occurs in children eight to 15 years of age, and it is one of the most commonly missed diagnoses in children. Slipped capital femoral epiphysis is classified as stable or unstable based on the stability of the physis. The condition is associated with obesity and growth surges, and it is occasionally associated with endocrine disorders such as hypothyroidism, growth hormone supplementation, hypogonadism, and panhypopituitarism. Patients usually present with limping and poorly localized pain in the hip, groin, thigh, or knee. Diagnosis is confirmed by bilateral hip radiography, which needs to include anteroposterior and frog-leg lateral views in patients with stable slipped capital femoral epiphysis, and anteroposterior and cross-table lateral views in patients with the unstable form. The goals of treatment are to prevent slip progression and avoid complications such as avascular necrosis and chondrolysis. Stable slipped capital femoral epiphysis is usually treated using in situ screw fixation. Treatment of unstable slipped capital femoral epiphysis usually involves in situ fixation, but there is controversy about the timing of surgery, value of reduction, and whether traction should be used. Classification
Classification of SCFE is based on the stability of the physis.10 If the patient is unable to ambulate even with crutches, the SCFE is considered unstable. If the patient is able to ambulate with or without crutches, the SCFE is considered stable.10 If the patient is unable to ambulate even with crutches, the SCFE is considered unstable.9 Stable SCFE accounts for about 90 percent of all slips.11 Classification is important because a stable SCFE generally has a better prognosis than an unstable SCFE, which has a higher rate of complications.12

Epidemiology
The prevalence of SCFE is 10.8 cases per 100,000 children.2,12 It is more common in boys than girls, as well as in blacks and Pacific Islanders, possibly because of increased body weight in these populations.12 The average age at diagnosis is 13.5 years for boys and 12.0 years for girls.12 SCFE presents bilaterally in 18 to 50 percent of patients.13-15 Some patients present sequentially (hips usually affected within 18 months of each other).10 There is a seasonal variation in the rate of SCFE in the northern United States, with increased rates in late summer and fall in patients who reside north of 40 degrees latitude.15,17 This may be caused by increased physical activity in the summer or may result from impaired vitamin D synthesis.

Patient information:
Etiology

The etiology of SCFE is thought to be multifactorial and may include obesity, growth surges, and, less commonly, endocrine disorders.\textsuperscript{18-21} Of children diagnosed with SCFE, 63 percent have a weight in the 90th percentile or higher.\textsuperscript{22,23} Related endocrine disorders include hypothyroidism, growth hormone supplementation, hypogonadism, and panhypopituitarism.\textsuperscript{2} An endocrine disorder should be considered in SCFE with unusual presentations, including patients who are younger than eight years, older than 15 years, or underweight.\textsuperscript{20}

History and Physical Examination

Table 1 outlines the differential diagnosis of a young patient presenting with hip pain. The most common symptoms of SCFE are limping and pain that is poorly localized to the hip, groin, thigh, or knee.\textsuperscript{8} Knee or distal thigh pain is the presenting symptom in 15 percent of patients with the condition.\textsuperscript{24} History of trauma to the area is rare.\textsuperscript{9,25}

On physical examination, the patient may be unable to bear weight with a severe slip. Limited internal rotation of the hip is the most telling sign in the diagnosis of SCFE.\textsuperscript{8} Obligatory external rotation is noted in the involved hip of patients with SCFE when the hip is passively flexed to 90 degrees\textsuperscript{1,4,8} (Figure 2). Unless the patient has bilateral SCFE, it is helpful to compare range of motion with the uninvolved hip.

Radiography

Radiography is needed for patients eight to 15 years of age with new-onset limping and pain in the hip, groin, thigh, or knee. It is important to inform the radiologist of the
clinical context and that SCFE is suspected so that the diagnosis can be ruled out. Radiography needs to include anteroposterior and frog-leg lateral views of both hips to diagnose stable SCFE (Figure 3). In unstable SCFE, anteroposterior and cross-table lateral views of the involved side should be compared with the uninvolved side because of the decreased range of motion of the hip. The radiologic signs of SCFE are shown in Figures 4 and 5.

Radiography is used to grade the severity of the slip in SCFE. The Wilson method measures the relative displacement of the epiphysis on the metaphysis in a frog-leg lateral radiograph. A mild slip involves epiphysis displacement less than one third of the width of the metaphysis; a moderate slip involves displacement between one third and one half of the width; and a severe slip involves displacement greater than one half of the width. The Southwick method measures the epiphyseal shaft angle on the frog-leg lateral radiograph (Figure 6). The angle is calculated by subtracting the epiphyseal shaft angle on the uninvolved side from that on the side with SCFE. A mild slip is less than 30 degrees, a moderate slip is between 30 and 50 degrees, and a severe slip is greater than 50 degrees.

Treatment

Once the diagnosis of SCFE is made, the patient should be placed on non-weight-bearing crutches or in a wheelchair and quickly referred to an orthopedic surgeon familiar with the treatment of SCFE. The initial goals of treatment are to prevent slip progression and avoid complications.
Prophylactic treatment of the contralateral hip in patients with SCFE is controversial, but it is not recommended in most patients. Prophylactic pinning may be indicated in patients at high risk of subsequent slips, such as patients with obesity or an endocrine disorder, or those who have a low likelihood of follow-up.11,15,30

STABLE SCFE

The standard treatment of stable SCFE is in situ fixation with a single screw1,4,9,31 (Figure 7). Case series and animal model studies have shown this to be a simple technique with low rates of recurrence and complications.4,9,31 After closure of the growth plate, progression of athletic activities may be allowed, including running and, eventually, participating in contact sports.1 Most patients with mild to moderate SCFE who are treated with in situ fixation have good to excellent long-term outcomes.11

UNSTABLE SCFE

Unstable SCFE is a much more severe injury than stable SCFE. The rate of osteonecrosis is as high as 20 to 50 percent in patients with the unstable form.9,32 Treatment goals are similar to those of stable SCFE with in situ fixation, but there is controversy as to the specifics of treatment, including timing of surgery, value of reduction, and whether traction should be used.1,31

Complications

AVASCULAR NECROSIS

Avascular necrosis occurs in up to 60 percent of patients with unstable SCFE.31 It is a serious complication associated with severe displacement and fixation with more than one screw.8,29 Avascular necrosis often leads to advanced and early degenerative osteoarthritis.33

CHONDROLYSIS

Chondrolysis is the acute loss of articular cartilage, which causes joint stiffness and pain.9 It is usually reported as a complication of surgical treatment of SCFE, but it can occur with the use of a hip spica cast and in untreated advanced SCFE. With the improvement of surgical techniques, the
incidence of chondrolysis has decreased from a rate of 5 to 7 percent to a rate of 1 to 2 percent in patients treated for SCFE.8,9
