Reducing Adverse Effects of Proton Pump Inhibitors

PAUL W. AMENT, PharmD; DANIEL B. DICOLA, MD; and MARY E. JAMES, MD
Excela Health Latrobe Family Medicine Residency Program, Latrobe, Pennsylvania

Proton pump inhibitors effectively treat gastroesophageal reflux disease, erosive esophagitis, duodenal ulcers, and pathologic hypersecretory conditions. Proton pump inhibitors cause few adverse effects with short-term use; however, long-term use has been scrutinized for appropriateness, drug-drug interactions, and the potential for adverse effects (e.g., hip fractures, cardiac events, iron deficiency, Clostridium difficile infection, pneumonia). Adults 65 years and older are more vulnerable to these adverse effects because of the higher prevalence of chronic diseases in this population. Proton pump inhibitors administered for stress ulcer prophylaxis should be discontinued after the patient is discharged from the intensive care unit unless other indications exist. HIP FRACTURE
A retrospective study in the United Kingdom found a substantially higher incidence of hip fractures in patients older than 50 years who used PPIs for more than one year, with higher fracture risk associated with longer treatment duration.12 A similar study found an increased fracture risk in patients using long-term PPIs who had at least one other risk factor, including diabetes mellitus, chronic renal diseases, and glucocorticoid use.13 In 2010, the FDA revised the labeling of all PPIs to include the increased risk of fractures of the hip, wrist, and spine.14

CARDIAC EVENTS
Risk factors for gastrointestinal bleeding in patients taking clopidogrel (Plavix) include previous gastrointestinal bleeding; advanced age; concomitant use of warfarin (Coumadin), glucocorticoids, or nonsteroidal anti-inflammatory drugs; and Helicobacter pylori infection. In 2007, the American College of Cardiology and the American Heart Association recommended the use of gastroprotective agents in patients with unstable angina or non–ST segment elevation myocardial
infarction who were taking aspirin and clopidogrel, and who had a history of gastrointestinal ulceration. Since that time, studies have suggested an increased risk of reinfarction in patients taking clopidogrel and a PPI other than pantoprazole (Protonix). There also may be an increased risk of rehospitalization with concomitant use of a PPI and clopidogrel following percutaneous angiography and treatment for acute coronary syndrome. Therefore, the American College of Cardiology and the American Heart Association suggest that physicians prescribe drugs other than PPIs, such as histamine H₂ antagonists (e.g., ranitidine [Zantac]), for patients taking aspirin and clopidogrel who require gastroprotection.

Studies show that PPIs block the effects of clopidogrel by inhibiting cytochrome P450 2C19 isozyme (CYP2C19), which converts clopidogrel to its active form. Although data strongly suggest an interaction between omeprazole and clopidogrel, the clinical significance of this interaction is unknown. Pantoprazole may be preferred over other PPIs in the setting of acute coronary syndrome or coronary stenting because it has a lower potential to inhibit CYP2C19.

In patients with concomitant atherosclerosis and a high risk of gastrointestinal bleeding, physicians should weigh the potential cardiovascular risks of PPIs against less effective alternatives, such as H₂ antagonists. The product information for clopidogrel has been changed to recommend avoiding concurrent use with omeprazole because it decreases the antiplatelet effectiveness of clopidogrel.

**IRON DEFICIENCY**

An increase in gastric pH is a normal physiologic change in the gastrointestinal tract of older persons and is exacerbated by long-term PPI use. It is unlikely that patients with normal iron stores will develop iron deficiency anemia solely from PPI use. However, patients with low baseline iron stores may be more susceptible to further iron depletion with concurrent PPI therapy.

**ENTERIC INFECTIONS**

Studies indicate an increased risk of diarrhea from *Clostridium difficile* and of other enteric infections in hospitalized patients taking PPIs and antibiotics. There is also an increased risk of recurrent *C. difficile* infection.

after hospital discharge in those taking PPIs.\textsuperscript{8} Acid suppression has been associated with an increased risk of \textit{Campylobacter} enteritis. An increase in acute viral gastroenteritis in children was reported in those treated with PPIs for gastroesophageal reflux disease.\textsuperscript{26} The proposed mechanism of action is a less acidic gastric environment, leading to increased bacterial colonization of the upper gastrointestinal tract.\textsuperscript{27}

**PNEUMONIA**

Acid suppression allows ingested pathogens to colonize the gastrointestinal tract and relocate to the respiratory tract.\textsuperscript{28} One study of older patients hospitalized for pneumonia found that initiating a PPI or \( \text{H}_2 \) antagonist at discharge significantly increased the likelihood of recurrent community-acquired pneumonia.\textsuperscript{9} Another study found a statistically significant increase in the risk of hospital-acquired pneumonia with PPI use.\textsuperscript{10} Physicians should weigh the risks versus benefits before initiating a PPI in patients being treated for pneumonia.\textsuperscript{11}

**GASTRIC ACID REBOUND**

Several studies have demonstrated that asymptomatic patients who are administered short-course PPI therapy develop rebound gastrointestinal symptoms after discontinuation.\textsuperscript{15,16} Patients reported clinically significant dyspeptic symptoms after discontinuation of a two-month course of esomeprazole (Nexium) compared with placebo (44 versus 15 percent).\textsuperscript{15} A similar study of pantoprazole in asymptomatic, \( H. \text{ pylori} \)-negative patients showed persistent rebound gastrointestinal symptoms for two weeks following discontinuation.\textsuperscript{16}

Discontinuation of PPIs may exacerbate the same symptoms physicians are aiming to treat, possibly because of rebound acid hypersecretion.\textsuperscript{15,16} This may explain why patients have difficulty discontinuing long-term PPI therapy.

**Stress Ulcer Prophylaxis**

Many patients admitted to the intensive care unit (ICU) have risk factors for stress ulcers, with active bleeding producing a higher rate of mortality.\textsuperscript{29} Significant risk factors associated with gastrointestinal bleeding include coagulopathy and mechanical ventilation exceeding 48 hours’ duration.\textsuperscript{30} Based on a review of 58 studies, stress ulcer prophylaxis is recommended by the Eastern Association for the Surgery of Trauma for patients with any of the following: mechanical ventilation longer than

48 hours, coagulopathy (e.g., platelet count less than \(50 \times 10^3\) per \(\mu L\) \([50 \times 10^3\) per \(L\)], international normalized ratio greater than 1.5, partial thromboplastin time greater than two times the normal control), traumatic brain injury, and major burn injury (more than 30 percent of body surface).\(^{30}\)

Effective options for stress ulcer prophylaxis include PPIs, \(H_2\) antagonists, antacids, and sucralfate (Carafate). No medication has been shown to be superior to another. Although the optimal duration of prophylaxis is not known, most experts suggest continuing therapy while the patient is in the ICU, when bleeding risk is highest. However, many patients continue to receive prophylaxis inappropriately when they are transferred to general medical units and continue therapy after discharge without clear medical indications.\(^{31}\) To minimize adverse outcomes, physicians should discontinue PPIs in patients when they are discharged from the ICU if there are no other indications for therapy.
