Myocardial Infarction: Management of the Subacute Period

MICHAEL G. MERCADO, MD, Naval Hospital Camp Pendleton Family Medicine Residency Program, Camp Pendleton, California
DUSTIN K. SMITH, DO, U.S. Naval Hospital Guam, Agana Heights, Guam
MICHAEL L. MCCONNON, MD, Naval Hospital Pensacola Family Medicine Residency Program, Pensacola, Florida

Optimal management of myocardial infarction in the subacute period focuses on improving the discharge planning process, implementing therapies early to prevent recurrent myocardial infarction, and avoiding hospital readmission. Evidence-based guidelines for the care of patients with acute coronary syndrome are not followed up to 25% of the time. Antiplatelet therapy, renin-angiotensin-aldosterone system inhibitors, beta blockers, and statins constitute the foundation of medical therapy. Early noninvasive stress testing is an important risk assessment tool, especially in patients who do not undergo revascularization. Discharge preparation should include a review of medications, referral for exercise-based cardiac rehabilitation, activity recommendations, education about lifestyle modification and recognition of cardiac symptoms, and a clear follow-up plan. Because nonadherence to medications is common in patients after a myocardial infarction and is associated with increased mortality risk, modifiable factors associated with medication self-discontinuation should be addressed before discharge. Structured discharge processes should be used to enhance communication and facilitate the transition from the hospital to the family physician’s care. (Am Fam Physician. 2013;88(9):581-588. Copyright © 2013 American Academy of Family Physicians.)

Cardiovascular disease causes one in six deaths in the United States annually.1 In 2008, medical costs of heart disease were an estimated $190 billion, and are projected to triple over the next 20 years.1 A myocardial infarction (MI), defined as clinical evidence of myocardial necrosis consistent with myocardial ischemia, is diagnosed every 34 seconds in the United States.1,2 Acute coronary syndrome (ACS), which encompasses non–ST elevation MI and ST elevation MI, resulted in 1.2 million hospital admissions in 2009.1

Studies show that care consistent with established guidelines results in decreased mortality during hospitalization and at six months postdischarge, but up to 25% of opportunities to provide guideline-recommended care are missed.3,4 Preventing readmissions is also a concern; in a study of 16,000 patients with ACS, 20% were rehospitalized within one year, highlighting a need for more effective discharge planning and care transitions.3

Family physicians, in partnership with a cardiovascular subspecialist, have a vital role in the management of MI during the subacute period. This period begins after a revascularization procedure has been performed or after the decision to not revascularize is made, and lasts for one to three months.6 This article focuses on the management of MI during this critical period, and emphasizes the importance of the care transition from the hospital to the outpatient setting.

Early Hospital Care
Irrespective of the timing or nature of the decision to revascularize, several therapies have proven benefit in reducing adverse cardiovascular events during the subacute period.
Myocardial Infarction

ANTIPLATELET THERAPY

Aspirin. An inhibitor of platelet aggregation, aspirin should be given to all patients with suspected ACS. A systematic review of 15 trials showed that aspirin therapy in patients who had experienced an MI reduced stroke, repeat MI, and death (absolute risk reduction [ARR] = 3.8%; number needed to treat [NNT] = 26). An adequate dosage in the acute period is 162 to 325 mg per day; the dosage should be reduced to 75 to 162 mg per day upon discharge and continued indefinitely for prevention of recurrent MI.6-11

P2Y12 Inhibitors. P2Y12 inhibitors, including clopidogrel (Plavix), prasugrel (Effient), and ticagrelor (Brilinta), represent a class of antiplatelet agents that, when used in combination with aspirin therapy, decrease major cardiovascular events in patients with ACS who are undergoing percutaneous coronary intervention.12-14 Guidelines suggest that this combination, known as dual antiplatelet therapy, continue for a minimum of 12 months in patients receiving drug-eluting stents and for up to 12 months in those receiving bare metal stents, but the optimal duration is unknown.8,9

The benefits of dual antiplatelet therapy in decreasing the combined end points of cardiovascular mortality, subsequent MI, and stroke were noted at 30 days through 12 months for clopidogrel when compared with placebo (ARR = 2.1%; NNT = 48), and at 15 months and 12 months with prasugrel and ticagrelor, respectively, when compared with clopidogrel.14-16 Of the three P2Y12 inhibitors, only ticagrelor has been shown to improve all-cause mortality.12-14 Guidelines from the American College of Cardiology (ACC) and the American Heart Association (AHA) advocate dual antiplatelet therapy using clopidogrel and ticagrelor for up to 12 months in conservatively treated patients after an MI, but the optimal length of treatment is unclear.9 Proton pump inhibitors are recommended for patients receiving dual antiplatelet therapy who have a history of or period. Figure 1 provides an overview of the subacute management of MI.6-10

Management of Myocardial Infarction

Acute management: aspirin or clopidogrel (Plavix), anticoagulation, fibrinolysis (if appropriate), selection of management strategy

- No coronary angiography
- Pursue coronary angiography

Initial management

- Initiate clopidogrel or ticagrelor (Brilinta)
- Evaluate LVEF

- LVEF > 40%
- LVEF ≤ 40%

- Pursue noninvasive testing

- Low risk of cardiac ischemia
- High risk of cardiac ischemia

- Perform coronary angiography

Revascularization

- Discontinue anticoagulant therapy
- Continue dual antiplatelet therapy for 12 months

- Discharge medications: aspirin, dual antiplatelet therapy if indicated, angiotensin-converting enzyme inhibitor or angiotensin receptor blocker, aldosterone blocker if indicated, beta blocker, nitroglycerin, proton pump inhibitor in patients with an increased risk of gastrointestinal bleeding, and statin

Discharge preparation: use a high-quality discharge process, perform a detailed medication review, initiate smoking cessation counseling and dietary education, provide exercise-based cardiac rehabilitation referral, review steps to manage ischemic symptoms, arrange for follow-up with a primary care physician and cardiologist

Figure 1. Overview of the subacute management of myocardial infarction. (LVEF = left ventricular ejection fraction.) Information from references 6 through 10.
risk factors for gastrointestinal bleeding.\textsuperscript{8,17} Clopidogrel is recommended for patients with aspirin intolerance or allergy, regardless of the initial management strategy.\textsuperscript{8,18}

**BETA BLOCKERS**

Several systematic reviews have established the long-term mortality benefits of beta-blocker therapy in patients who have had an MI.\textsuperscript{19-20} The AHA recommends that oral beta-blocker therapy be initiated in all patients without contraindications within 24 hours after an MI, and continued at discharge.\textsuperscript{6,7,10} However, a Cochrane review that investigated antihypertensive agents initiated within 24 hours of a cardiovascular event found no mortality benefit from beta-blocker therapy within the first month.\textsuperscript{21} In patients with a left ventricular ejection fraction (LVEF) of 40% or less, beta-blocker therapy should be titrated gradually and continued indefinitely.\textsuperscript{6,7} Bisoprolol (Zebeta), carvedilol (Coreg), and metoprolol have exhibited a mortality benefit in patients with a reduced LVEF after an MI.\textsuperscript{22} Guidelines suggest using beta-blockers for at least three years in patients with preserved systolic function, but this recommendation is based on limited data.\textsuperscript{7} One prospective cohort study of 14,043 patients with a remote history of MI concluded that beta-blocker use may not improve cardiovascular outcomes.\textsuperscript{23}

**RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM INHIBITORS**

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers. Angiotensin-converting enzyme (ACE) inhibitors are strongly recommended after an MI in patients with hypertension, diabetes mellitus, an LVEF of 40% or less, or chronic kidney disease.\textsuperscript{6,11} Randomized controlled trials (RCTs) have established that ACE inhibitors reduce mortality in patients who have had an MI.\textsuperscript{24-26} One review of 22 RCTs concluded that early (within 48 hours) administration of ACE inhibitors after an MI reduced mortality in as early as one month (NNT = 167), and the benefits were greater at one year for early and late administration, with an ARR of 3.7% (NNT = 27) and 2.2% (NNT = 45), respectively.\textsuperscript{26} A Cochrane review concluded that ACE inhibitors administered within 24 hours of a cardiovascular event can prevent three to five deaths per 1,000 patients at 10 days.\textsuperscript{21} Unless contraindicated, ACE inhibitors should be continued indefinitely for prevention of recurrent cardiovascular events.\textsuperscript{8}

Angiotensin receptor blockers are recommended in patients who have indications for, but cannot tolerate, ACE inhibitors.\textsuperscript{6,8,10} Compared with monotherapy, combination therapy with ACE inhibitors and angiotensin receptor blockers leads to increased adverse events with no mortality benefit in patients after an MI, and is not recommended.\textsuperscript{27} ACE inhibitors and angiotensin receptor blockers should be avoided in patients with hyperkalemia, hypotension, and acute renal failure until these conditions resolve.\textsuperscript{10}

**Aldosterone Blockers.** Based on the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study, aldosterone blockers initiated as early as three days after an MI reduced all-cause mortality and cardiac death (ARR = 1.4%; NNT = 71) compared with placebo in patients with a low LVEF and signs of heart failure.\textsuperscript{28} Guidelines from the ACC/AHA recommend the use of aldosterone blockers in patients who have heart failure or diabetes, have an LVEF of 40% or less, are receiving ACE inhibitors and beta blockers, and have a serum potassium level less than 5.0 mEq per L (5.0 mmol per L) and a creatinine clearance greater than 30 mL per minute per 1.73 m\textsuperscript{2} (0.50 mL per second per m\textsuperscript{2}).\textsuperscript{6,8,10}

**STATIN THERAPY**

The role of statins in reducing mortality and ACS in patients with cardiovascular disease is well established.\textsuperscript{6,29} Consequently, current guidelines advocate initiating these agents before discharge, despite questionable mortality benefit in the subacute period, and continuing therapy indefinitely.\textsuperscript{6,8,10,29} A Cochrane review found that early initiation of statins in patients with ACS reduced episodes of unstable angina within four months without decreasing mortality or recurrent MI.\textsuperscript{29} A meta-analysis of 21 trials concluded that statins initiated as early as one day before percutaneous coronary intervention reduced the risk of postprocedural MI (ARR = 6%; NNT = 17) and reduced atrial fibrillation after coronary artery bypass grafting.\textsuperscript{30} Although the choice of statin does not matter, higher doses may yield more benefits. An RCT of 4,162 patients hospitalized for ACS found a 29% reduction in recurrent unstable angina and a 14% reduction in revascularization in patients receiving 80 mg per day of atorvastatin (Lipitor) compared with those receiving 40 mg per day of pravastatin (Pravachol).\textsuperscript{31} Consequently, high-dose atorvastatin may be considered in patients with ACS who are already receiving a lower dose or a less potent statin. The ACC and AHA recommend obtaining low-density lipoprotein cholesterol measurements within 24 hours of hospitalization as part of a cardiac risk assessment and guide to initiating lipid-lowering therapy.\textsuperscript{6,10}

**Noninvasive Testing**

Noninvasive testing, with or without imaging, is an important risk-assessment tool in patients who have had an MI but are not undergoing angiography. LVEF assessment is essential and should guide decisions about
The testing modality is based on exercise tolerance, baseline electrocardiography, and test availability. Intermediate- to low-risk patients who have been stable for 48 to 72 hours are candidates for symptom-limited stress testing. Guidelines from the ACC/AHA recommend submaximal exercise stress testing at four to six days, or symptom-limited stress testing at two to three weeks if predischarge testing was not performed. One study found early symptom-limited stress testing (three to seven days after MI) comparable to late testing (one month postdischarge) for diagnostic and prognostic evaluation, but noted that 50% of cardiovascular events within one year of follow-up occurred within the first month, making earlier testing the preferred option. However, data addressing the relative safety of early symptom-limited stress testing are scant.

Preparing for Discharge
A multidisciplinary approach before discharge includes medication review, referral for cardiac rehabilitation, activity recommendations, education about lifestyle modifications and recognition of cardiac symptoms, and a clear follow-up plan. Inadequate communication can hamper transitions of care; a review of 73 studies found that discharging physicians directly communicated with the patient’s primary care physician only 3% to 20% of the time. Project RED (Re-Engineered Discharge) is a standardized, patient-centered discharge process that can be applied to patients with MI. An RCT of 749 adults with multiple medical conditions who were hospitalized in an urban medical center showed a 30% decrease in combined readmission rates and emergency department visits within 30 days of discharge when Project RED was implemented. Table 1 summarizes the components of this quality-focused discharge process.

has been shown to improve cardiovascular and all-cause mortality rates.\textsuperscript{41,42} Guidelines encourage setting a goal of at least 150 minutes per week of moderate-intensity aerobic activity, such as brisk walking.\textsuperscript{8} Smoking cessation rates improve in patients with cardiovascular disease when behavioral interventions are initiated in the hospital setting and are coupled with one month of supportive contact.\textsuperscript{43} The addition of nicotine replacement therapy increases the likelihood of cessation and is safe in patients with ACS.\textsuperscript{43,44}
Postdischarge Interventions

CARDIAC REHABILITATION

The ACC and AHA recommend cardiac rehabilitation for patients with non–ST elevation MI or ST elevation MI.6,10 A Cochrane review found a 13% reduction in all-cause mortality and a 26% reduction in cardiovascular mortality in patients who underwent an exercise-based rehabilitation program, with similar results in those who underwent comprehensive (exercise and dietary management) programs.45 Specifically, reductions were noted in all-cause and cardiovascular mortality in patients who had follow-up at or beyond 12 months. In addition to their mortality benefit, these programs improve fitness, symptoms, lipid profiles, stress level, and overall well-being.46 Although benefits are clear, cardiac rehabilitation remains an underutilized resource. A Medicare claims data analysis found that it was used in only 14% of patients hospitalized for MI, emphasizing the need for its inclusion in a comprehensive discharge plan.47

ACTIVITY RECOMMENDATIONS

Guidelines from the ACC/AHA for management of non–ST elevation MI advise that patients may begin walking soon after discharge, resume sexual activity in as early as one week, and drive within three weeks after symptom resolution, although recovery times will vary depending on individual circumstances.6 Air travel should be avoided for two weeks unless the patient is symptom free, possesses nitroglycerin, has a traveling partner, and avoids situations requiring increased physical demands.6

ACE = angiotensin-converting enzyme; MI = myocardial infarction.

A = consistent, good-quality patient-oriented evidence; B = inconsistent or limited-quality patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. For information about the SORT evidence rating system, go to http://www.aafp.org/afpsort.
After ST elevation MI, patients are encouraged to return to physical activity as tolerated, ideally with guidance after an exercise stress test.10

**RECOGNITION OF CARDIAC SYMPTOMS**

Patients who have had an MI and their families should be taught to recognize cardiac symptoms, initiate the emergency response system, and use prescribed nitroglycerin. Resources for cardiopulmonary resuscitation training programs should be readily available.10

**FOLLOW-UP VISITS**

Patients who have had an MI should have follow-up appointments prescheduled with their cardiologist and primary care physician, and these appointments should be included in the discharge summary. Components of an effective follow-up visit include a review of symptoms, medication reconciliation, cardiovascular risk assessment, psychosocial status (including screening for depression), activity limitations, and referrals to cardiac rehabilitation if not already done.10
