Newborn respiratory distress presents a diagnostic and management challenge. Newborns with respiratory distress commonly exhibit tachypnea with a respiratory rate of more than 60 respirations per minute. They may present with grunting, retractions, nasal flaring, and cyanosis. Common causes include transient tachypnea of the newborn, respiratory distress syndrome (RDS), meconium aspiration syndrome, pneumonia, sepsis, pneumothorax, persistent pulmonary hypertension of the newborn, and delayed transition. Congenital heart defects, airway malformations, and inborn errors of metabolism are less common etiologies. Clinicians should be familiar with updated neonatal resuscitation guidelines. Initial evaluation includes a detailed history and physical examination. The clinician should monitor vital signs and measure oxygen saturation with pulse oximetry, and blood gas measurement may be considered. Chest radiography is helpful in the diagnosis. Blood cultures, serial complete blood counts, and C-reactive protein measurement are useful for the evaluation of sepsis. Most neonates with respiratory distress can be treated with respiratory support and noninvasive methods. Oxygen can be provided via bag/mask, nasal cannula, oxygen hood, and nasal continuous positive airway pressure. Ventilator support may be used in more severe cases. Surfactant is increasingly used for respiratory distress syndrome. Using the INSURE technique, the newborn is intubated, given surfactant, and quickly extubated to nasal continuous positive airway pressure. Newborns should be screened for critical congenital heart defects via pulse oximetry after 24 hours but before hospital discharge. Neonatology consultation is recommended if the illness exceeds the clinician’s expertise and comfort level or when the diagnosis is unclear in a critically ill newborn. (Am Fam Physician. 2015;92(11):994-1002. Copyright © 2015 American Academy of Family Physicians.)

Newborn respiratory distress occurs in about 7% of deliveries. Respiratory distress syndrome, which occurs primarily in premature infants, affects about 1% of newborns, resulting in about 860 deaths per year. With increased survival of preterm and late preterm infants, management of respiratory distress in newborns has become challenging. Because early recognition improves the care of these newborns, clinicians must be familiar with its diagnosis and treatment. Reduction of premature births and cesarean deliveries decreases respiratory distress cases, with prenatal care being crucial to prevention. Women with inadequate prenatal care may deliver babies with lower birth weights and increased risk of admission to the neonatal intensive care unit. Antenatal corticosteroid use in threatened preterm deliveries from 24 to 34 weeks’ gestation significantly reduces the incidence and severity of respiratory distress. Because cesarean delivery is a risk factor for respiratory distress, especially in premature infants, reducing these surgeries when possible could reduce the incidence of the condition.

Clinical Presentation

Tachypnea is the most common presentation in newborns with respiratory distress. A normal respiratory rate is 40 to 60 respirations per minute. Other signs may include nasal flaring, grunting, intercostal or subcostal retractions, and cyanosis. The newborn may also have lethargy, poor feeding, hypothermia, and hypoglycemia.

The most common causes of respiratory distress in newborns are transient tachypnea of the newborn (TTN), respiratory distress syndrome (RDS), meconium aspiration syndrome, pneumonia, sepsis, pneumothorax, and delayed transition. Rare causes include choanal atresia; diaphragmatic hernia;
tracheoesophageal fistula; congenital heart disease; and neurologic, metabolic, and hematologic disorders. The differential diagnosis of newborn respiratory distress is listed in Table 1.8

Rarely, newborns with RDS develop chronic lung disease or bronchopulmonary dysplasia. Definitions have been established for bronchopulmonary dysplasia severity (Table 2).9 Newborns with bronchopulmonary dysplasia may have nutritional failure, have neurodevelopmental delays, and require oxygen for a longer period with higher hospital readmission rates.10

### Diagnosis

A careful history and physical examination are imperative in the evaluation of newborns with respiratory distress. Additional workup options are included in Table 3.8

Laboratory data can assist in the diagnosis. Complete blood counts with an immature to total neutrophil ratio of more than 0.2 is suggestive of infection. This ratio can be altered by stress, crying, and labor induced with oxytocin (Pitocin).11 Although the immature to total neutrophil ratio has significant sensitivity and negative predictive value, it has poor positive predictive accuracy as a one-time test and is falsely elevated in 50% of infants without an infection.11 C-reactive protein levels of less than 10 mg per L (95.24 nmol per L) rule out sepsis with a 94% negative predictive value when obtained 24 and 48 hours after birth.12 Glucose levels should also be measured because hypoglycemia can be a cause and consequence of respiratory distress.

### General Treatment Principles

Treatment of neonatal respiratory distress should be both generalized and disease-specific, and follow updated neonatal resuscitation protocols. Figure 1 is an algorithm for the evaluation and management of newborn respiratory distress.8

### RESPIRATORY SUPPORT

Oxygenation can be maintained by delivering oxygen via bag/mask, nasal cannula, oxygen hood, nasal continuous positive airway pressure (N-CPAP), or ventilator...
support. Resuscitation with 100% oxygen may increase neonatal mortality compared with ambient air.13 Blended oxygen, with the fraction of inspired oxygen ranging from 21% to 50% oxygen, stabilizes premature newborns, and pulse oximetry monitors are used to maintain saturations around 90%.14

Noninvasive ventilation, commonly using N-CPAP, has become the standard respiratory treatment over invasive intubation. N-CPAP has decreased transfers to tertiary care centers with a number needed to treat of 7.3 and a potential cost reduction of $10,000 per case.15 Nasal intermittent positive pressure ventilation can also be used. In preterm newborns with RDS, nasal intermittent positive pressure ventilation has been shown to reduce the relative need for mechanical ventilation by 60%.16 Conventional mechanical ventilation is reserved for more severe cases.

SURFACTANT REPLACEMENT

Prophylactic and rescue therapy with natural surfactants in newborns with RDS reduces air leaks and mortality. Neonatal type II pneumocytes produce surfactant in the third trimester to prepare for air breathing. Without surfactant, there is higher pulmonary surface tension, atelectasis, and ventilation/perfusion mismatch resulting in hypoxia, hypercapnia, and acidosis.

The minimum required amount of surfactant therapy is 100 mg per kg. An initial dose of 200 mg per kg leads to a statistically significant improvement in oxygenation and decreased need to retreat, although there is no survival benefit.17,18 A Cochrane review showed that the technique known as INSURE (intubate, administer surfactant, extubate to N-CPAP) led to a 67% relative risk reduction for mechanical ventilation and about a 50% relative risk reduction for air leak syndromes and progression to bronchopulmonary dysplasia.19 The American Academy of Pediatrics recently released guidelines for surfactant use in newborns with respiratory distress.20

OTHER SUPPORT

Adequate fluid and electrolyte balance should be maintained. Oral feedings are withheld if the respiratory rate

Newborn Respiratory Distress

The most common etiology of respiratory distress in newborns is TTN, which occurs in about five or six per 1,000 births.\textsuperscript{22} It is more common in newborns of mothers with asthma.\textsuperscript{23} Newborns with TTN have a greater risk of developing asthma in childhood; in one study, this association was stronger in patients of lower socioeconomic status, nonwhite race, and males whose mothers did not have asthma.\textsuperscript{24} TTN results from delayed reabsorption and clearance of alveolar fluid. Postdelivery prostaglandin release distends lymphatic vessels, which removes lung fluid as pulmonary circulation increases with the initial fetal breath. Cesarean delivery without labor bypasses this process and is therefore a risk factor for TTN.\textsuperscript{25} Surfactant deficiency may play a role in TTN. Research indicates a decreased count of lamellar bodies in the gastric aspirate and decreased surfactant phospholipid concentrations in the tracheal aspirate in cases of TTN. However, treating TTN with surfactant is not indicated.\textsuperscript{26,27} TTN presents within two hours of birth and can persist for 72 hours. Breath sounds can be clear or reveal rales on auscultation. The higher the respiratory rate at onset, the longer TTN is likely to last.\textsuperscript{28,29} Chest radiography findings (Figure 2)\textsuperscript{30} support a clinical diagnosis, revealing hyperexpansion, perihilar densities with fissure fluid, or pleural effusions. Blood gases may show hypoxemia, hypercapnia, or respiratory acidosis.

Because TTN is self-limited, treatment is supportive. Furosemide (Lasix) may cause weight loss and hyponatremia, and it is contraindicated despite the excess pulmonary fluid present in newborns with TTN.\textsuperscript{31} Fluid restriction in TTN is beneficial, reducing the duration of respiratory support and hospital-related costs.\textsuperscript{32} Inhaled albuterol reduces tachypnea duration and the need for oxygen therapy, although standardized guidelines are still needed.\textsuperscript{33} Antibiotics are not indicated in TTN.\textsuperscript{34} Antenatal corticosteroids given 48 hours before elective cesarean delivery at 37 to 39 weeks’ gestation reduce TTN incidence, although it is unclear whether delaying cesarean delivery until 39 weeks’ gestation is preferable.\textsuperscript{6}

Etiologies

The causes of respiratory distress in newborns are summarized in Table 4.\textsuperscript{5} The following conditions are listed in order of frequency and/or severity.

Management of Respiratory Distress in Newborns

Newborn presents with respiratory distress

- Consider patient/maternal history and risk factors to aid in differential diagnosis
- Assess degree of distress

Severe distress (severe grunting or nasal flaring, apnea, cyanosis)
- Resuscitation
- Pulse oximetry
- Supplemental oxygen
- Chest radiography
- Complete blood count, C-reactive protein measurement, blood glucose meter check

Mild distress (mild tachypnea or grunting)
- Observe for 10 to 20 minutes
- Consider blood glucose meter check
- Maintain warm environment

Clinical improvement?

No
- Laboratory testing and chest radiography as above if not done previously
- Nasal continuous positive airway pressure, INSURE strategy\textsuperscript{*}
- Treatment based on results of testing
- Judicious antibiotic use
- Consider neonatal intensive care unit consultation or transfer

Yes
- Routine newborn nursery
- Treatment based on results of testing if performed

Figure 1. Suggested algorithm for management of respiratory distress in newborns.

\textsuperscript{*}—Intubate, administer surfactant, extubate to nasal continuous positive airway pressure; mostly used in premature newborns.

exceeds 60 respirations per minute to prevent aspiration. A neutral thermal environment reduces the newborn’s energy requirements and oxygen consumption.\textsuperscript{21} If the illness exceeds the clinician’s expertise and comfort level or the diagnosis is unclear in a critically ill newborn, neonatology should be consulted.

Etiologies

The causes of respiratory distress in newborns are summarized in Table 4.\textsuperscript{5} The following conditions are listed in order of frequency and/or severity.
Newborn Respiratory Distress

RESPIRATORY DISTRESS SYNDROME

Newborns born before 34 weeks’ gestation may have respiratory distress secondary to surfactant deficiency and lung immaturity. RDS is more common in white males and newborns born to mothers with diabetes mellitus.35,36

RDS symptoms (i.e., tachypnea, grunting, retractions, and cyanosis) occur immediately after birth. Chest radiography (Figure 37) shows a diffuse ground-glass appearance with air bronchograms and hypoexpansion, and blood gas measurements show hypoxemia and acidosis. Symptoms normally worsen in the first 12 to 24 hours. With advances in treatment such as surfactant and N-CPAP, most newborns with RDS recover without long-term effects. Bronchopulmonary dysplasia can occur in complicated cases, leading to recurrent wheezing, asthma, and higher hospital admission rates later in life.38

Antenatal corticosteroids given between 24 and 34 weeks’ gestation decrease RDS risk with a number needed to treat of 11.39 A single dose of antenatal corticosteroids is beneficial if given more than 24 hours before delivery and provides coverage for seven days. The use of repetitive antenatal corticosteroid doses to prevent RDS is debatable, but no more than two courses are recommended.40

**MECONIUM ASPIRATION SYNDROME**

Meconium-stained amniotic fluid is present in approximately 10% to 15% of deliveries, although the incidence of meconium aspiration syndrome is only 1%. Because meconium excretion often represents fetal maturity, meconium aspiration syndrome occurs in term and post-term newborns. Meconium is a conglomerate of desquamated cells, bile pigments, pancreatic enzymes, and amniotic fluid. Although sterile, it can lead to bacterial infection, irritation, obstruction, and pneumonia.

Meconium aspiration syndrome presents at birth as marked tachypnea, grunting, retractions, and cyanosis. Examination may reveal a barrel-shaped chest, with rales and rhonchi heard on auscultation. Chest radiography (Figure 4) may show bilateral fluffy densities with hyperinflation. Treatment includes N-CPAP and supplemental oxygen. Ventilator support may be needed in more severe cases.

Perineal neonatal suctioning for meconium does not prevent aspiration. If the infant is hypotonic at birth, intubation and meconium suctioning are advised. Vigorous infants receive expectant management.

**NEONATAL SEPSIS AND PNEUMONIA**

Sepsis can occur in full-term and preterm infants and has an incidence of one or two per 1,000 live births. Symptoms may begin later in the newborn period. Risk factors include membrane rupture more than 18 hours before delivery, prematurity, and maternal fever. Common pathogens include group B streptococci, Escherichia coli, Listeria monocytogenes, Haemophilus influenzae, Staphylococcus aureus, and gram-negative organisms. Universal screening and antepartum antibiotics for group B streptococci carriers reduce early-onset disease. However, 5,701 patients need to be screened and

Newborn Respiratory Distress

Case Studies

CASE 1
A male infant was born at 39 3/7 weeks estimated gestational age via cesarean delivery because of nonreassuring fetal heart tones. Maternal labor history included clear fluid rupture of amniotic membranes for seven hours. Antenatal screening was negative for group B streptococci. Tachypnea without cyanosis was noted approximately four hours after birth. Physical examination revealed a pulse of 152 beats per minute and respiratory rate of 82 respirations per minute with wet sounding breaths. Mild intercostal retractions were noted. Chest radiography showed increased pulmonary vascularity. A blood glucose measurement was 58 mg per dL (3.2 mmol per L). Immature to total neutrophil ratio was 0.12. Oral feedings were held because of tachypnea, and oxygen was given at 2 L by nasal cannula. Over the next 12 hours, the tachypnea decreased to 50 respirations per minute, and oral feeding was successful.

Given the onset of tachypnea and risk factors (male sex, non–meconium-stained fluid, and cesarean delivery), this case reflects transient tachypnea of the newborn.

CASE 2
A female infant was born at 31 5/7 weeks estimated gestational age via spontaneous vaginal delivery in the context of placental abruption. The newborn weighed 4 lb, 2 oz and had Apgar scores of 5 and 5. Tachypnea, retractions, and grunting occurred soon after birth. Physical examination revealed a pulse of 165 beats per minute, respiratory rate of 94 respirations per minute, and blood pressure of 64/44 mm Hg with coarse breath sounds. Blood glucose measurement was 47 mg per dL (2.6 mmol per L), immature to total neutrophil ratio was 0.18, and C-reactive protein level was 2.4 mg per L (22.86 nmol per L). Arterial blood gas measurements were pH of 7.25, PCO₂ of 65 mm Hg (8.6 kPa), and PO₂ of 40 mm Hg (5.3 kPa).

 Nasal continuous positive airway pressure was started immediately, interrupted as natural surfactant was administered endotracheally in the delivery room, and resumed while the newborn’s temperature was stabilized. The child was admitted to the neonatal intensive care unit.

Given the immediate onset of tachypnea, this case reflects respiratory distress syndrome. The INSURE (intubate, administer surfactant, extubate to nasal continuous positive airway pressure) technique is emphasized.

1,191 patients treated to prevent one infection. A risk calculator can be used to estimate the probability of neonatal early-onset infection.

Early-onset pneumonia occurs within the first three days of life, resulting from placental transmission of bacteria or aspiration of infected amniotic fluid. Late-onset pneumonia occurs after hospital discharge. Bacterial pathogens are similar to those that cause sepsis.

Serial complete blood counts, C-reactive protein measurements, and blood cultures help with diagnosis and treatment. Intravenous antibiotics are administered if bacterial infection is suspected. Ampicillin and gentamicin are common antibiotics for early-onset infections, whereas vancomycin and/or oxacillin with an aminoglycoside are used for late-onset infections. Antibiotics should be used judiciously. Treatment duration depends on clinical condition and laboratory findings.

PNEUMOTHORAX
Pneumothorax occurs if pulmonary space pressure exceeds extrapleural pressure, either spontaneously or secondary to an infection, aspiration, lung deformity, or ventilation barotrauma. Spontaneous pneumothorax occurs in 1% to 2% of term births, and more often in premature births and in newborns with RDS or meconium aspiration syndrome. A small pneumothorax may be asymptomatic.

Although transillumination can be helpful, chest radiography confirms the diagnosis. Symptomatic newborns need supplemental oxygen. Tension pneumothorax requires immediate needle decompression or chest tube drainage.

PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN
Delicate physiologic mechanisms allow for circulatory transition after birth with a resultant decrease in pulmonary vascular resistance. Failure of these mechanisms causes increased pulmonary pressures and right-to-left shunting, resulting in hypoxemia. This failure can be caused by meconium aspiration syndrome, pneumonia or sepsis, severe RDS, diaphragmatic hernia, and pulmonary hypoplasia. Severe persistent pulmonary hypertension of the newborn (PPHN) occurs in two out of 1,000 live births. Risk factors include maternal diabetes, cesarean delivery, maternal obesity, and black race. Maternal use of a selective serotonin reuptake inhibitor is associated with the condition. Data show only a small absolute risk.

With PPHN, respiratory distress occurs within 24 hours of birth. On examination, a loud second heart sound and systolic murmur may be heard. Oxygen saturation or PaO₂ increases when 100% oxygen is provided. Echocardiography should be performed to confirm the diagnosis. PPHN is treated with oxygen and other support. In serious cases, ventilator or vasopressor...
support and/or use of pulmonary vasodilators such as inhaled nitric oxide or sildenafil (Revatio) may be helpful. A few cases require extracorporeal membrane oxygenation.

CONGENITAL HEART DEFECTS

Congenital heart defects occur in about 1% of births in the United States annually. One-fourth of cases are critical, necessitating surgery in the first year, and one-fourth of those newborns do not survive the first year.56 Newborns with cyanotic heart disease present with intense cyanosis that is disproportionate to respiratory distress. Cardiac murmur may be heard on examination. Decreases in femoral pulses and lower extremity blood pressures may indicate coarctation of the aorta. Providing 100% oxygen will not improve oxygen saturation. Chest radiography and electrocardiography may indicate congenital structural abnormalities, and echocardiography can confirm the diagnosis.

The U.S. Department of Health and Human Services recommends pulse oximetry over physical examination alone to screen for critical congenital heart defects.53 Newborns should be screened before hospital discharge, but at least 24 hours after birth. The cost of treating one critical congenital heart defect exceeds the cost of screening more than 2,000 newborns, with 20 infant deaths prevented with screening.54,55 Pulse oximetry screening for critical congenital heart defects is becoming standard practice before hospital discharge.

DELAYED TRANSITION

The diagnosis of delayed transition is made retrospectively when symptoms cease without another identified etiology. It results from retained fluid and incompletely expanded alveoli from a precipitous vaginal delivery, as pathophysiologic mechanisms have not had sufficient time to adjust to extrauterine life. Treatment is supportive until the distress resolves a few hours after transition concludes.

Data Sources: A PubMed search was completed in Clinical Queries using the key terms newborn, distress, respiratory, meconium, and tachypnea. The search included meta-analyses, randomized controlled trials, clinical trials, and reviews. Also searched were DynaMed, Clinical Evidence, the Cochrane database, Essential Evidence Plus, the National Guideline Clearinghouse database, and the American Academy of Pediatrics. Search dates: October 2014 to March 2015.
